Abstract. In this article we build multi-objective hyper-heuristics (MOHHs), using the multi-objective evolutionary algorithm NSGA-II, for solving irregular 2D cutting stock problems under a bi-objective minimization schema; having a trade-off between the number of sheets used to fit a finite number of pieces and the time required to perform the placement of these pieces. We solve this problem using a multi-objective variation of hyper-heuristics called MOHH, whose main idea consists of finding a set of simple heuristics which can be combined to find a general solution; where a single heuristic is applied depending on the current condition of the problem, instead of applying a unique single heuristic during the whole placement process. MOHHs are built after going through a learning process using the NSGA-II, which evolves combinations of condition-action rules producing at the end a set of Pareto-optimal MOHHs. We test the approximated MOHHs on several sets of benchmark problems and present the results.

Keywords: Hyper-Heuristics, Multi-Objective Optimization, Evolutionary Computation, Cutting Problems.

Resumen. En este artículo se construyen Híper-Heurísticas Multi-Objetivo (MOHH por las siglas en Inglés), utilizando el algoritmo evolutivo multi-objetivo NSGA-II, para solucionar problemas de corte irregular en 2D empleando un esquema bi-objetivo; teniendo un balance entre el número de hojas usadas para ajustar un número finito de piezas y el tiempo requerido para realizar el acomodo de las piezas. Este problema es resuelto usando las MOHHs, cuya idea principal consiste en encontrar un conjunto de heurísticas simples que puedan ser combinadas para encontrar una solución general; donde una heurística simple es utilizada dependiendo de la condición actual del

problema, en vez de aplicar una única heurística simple durante todo el proceso de acomodo. Las MOHHs son construidas a través de un proceso de aprendizaje evolutivo utilizando el NSGA-II, el cual evoluciona combinaciones de reglas condición-acción produciendo al final un conjunto de MOHHs Pareto-óptimas. Las MOHHs construidas son probadas en diferentes conjuntos de problemas y los resultados obtenidos son presentados aquí.

1 Introduction

Bin packing and cutting stock problems are well-known classical problems with many applications in areas like operational research, logistics and related subjects. The basic idea and main goal is to fit a finite number of pieces into a minimum number of bins, subject to a practical set of restrictions. For small combinatorial problems, exact methods like linear programming can be applied. However, when larger and more complex problems appear, exact solutions are not feasible since the search space grows exponentially, and so does the time to find the optimal solution. Various heuristic and approximate approaches that guarantee finding near optimal solutions have been proposed ([5], [15]). However, no reliable method that can solve a large variation of instances of a given problem has been found.

A hyper-heuristic (HH) is a method used to define a high-level heuristic that controls low-level heuristics [2]. The hyper-heuristic decides when

and where to apply each single low-level heuristic, depending on the given problem state and the search space. In recent work ([17], [18]), evolutionary approaches have been used to generate hyper-heuristics for the 2D regular and irregular cutting stock problems ([19], [20], [21]). These methods assemble a combination of single heuristics (each concerned with selection and placement of a piece), and this combination takes into account the quality of partial solutions provided by the single heuristics.

Nevertheless, the majority of the works devoted to tackle the problems of bin packing and cutting stock are focused on mono-objective solutions like minimizing the trim loss or the number of bins used; however, these problems are naturally multi-objective, since several (opposite) objectives can be optimized at the same time. Just recently some works devoted to multi-objective cutting and packing problems have started to emerge ([11], [16]). The present article intends to contribute with another perspective of solution for these problems. In particular we focus on problems involving cutting 2D irregular pieces where two objectives need to be minimized: the number of sheets used to cut a finite number of pieces with irregular convex shapes and the time required to perform the placement of all the pieces inside the sheets.

The aim of this paper is to present a method based on the Multi-Objective Evolutionary Algorithm (MOEA) [6] NSGA-II [8] to approximate generalized Multi-Objective Hyper-Heuristics (MOHHs) in order to solve the cutting-stock problem described above. Our model is an adaptation of the one presented in [21]. Here we use NSGA-II with a variable-length representation, where this algorithm evolves combinations of condition-action rules through a learning process, producing at the end a set of Pareto-optimal MOHHs. Finally, we test the approximated MOHHs on several sets of benchmark problems. The results of the proposed model are truly encouraging.

The remainder of this paper is organized as follows. Section 2 describes with more detail the bi-objective cutting-stock problem. Section 3 gives a description of the NSGA-II algorithm, the hyper-heuristics and the single heuristics to be

combined in the proposed solution model based on MOHH, which is presented in section 4. This is followed by the experimental setup, the results and discussion in section 5. Finally, in section 6 we include our conclusions and some ideas for future work.

2 Bi-Objective Cutting Stock Problem

The cutting stock and packing problems are among the earliest problems in the literature of operational research. In 1939, Kantorovich [14] studied applications in all the industries whose products were in a flat sheet form. An extensive literature on these problems and their applications has developed since. For example, Golden in [12] gives an abstract description of a variety of different solution methods; in [5] Chen et al. discuss a number of solution methods, and Dyckhoff in [9] and Wäscher in [22] list a number of solution methods and applications and presents a systematic categorization of cutting and packing problems.

In this paper we are interested into solve instances of problems considered as 2D cutting stock problems with convex irregular shape pieces. We can define formally this type of problems as: given a set $L=(a_1, a_2, \dots, a_n)$ of pieces to be cut, each one of size $s(a_i) \in (0, A_0]$, from a set of m cutting stock sheets of size A_0 , the multi-objective goal of cutting the pieces from the sheets can be expressed as follows:

$$\text{minimize } z_1 = \sum_{i=1}^m y_i \quad (1)$$

$$\text{minimize } z_2 = \sum_{i=1}^n t_i \quad (2)$$

$$\text{s.t. } \sum_{i=1}^n s(a_i) \leq mA_0$$

where expression 1 minimizes the number y_i of needed sheets to fit all the pieces, and expression 2 minimizes the time to place all the pieces inside those sheets, where t_i indicates the required time to put the piece a_i inside a sheet, using a given heuristic. The restriction avoids that the total area of the pieces is bigger than the area of the sheet; and in addition, in this work we consider for each

problem that all the sheets must have the same size and in all the cases the same square shape. An example of the type of problems we are interested can be seen in Figure 1.

Fig. 1. Example of an irregular cutting problem

Intuitively, the two objective functions presented above are of conflicting nature. While a large number of sheets allows the placement of all the pieces very fast, having $z_2 \rightarrow 0$, the trim of material will be also large; on the other hand, a solution with $z_1 \rightarrow 0$, will tend to require more time to place all the pieces in the best position in order to do not waste material. This means that not a single solution x exists in the set of feasible solutions \mathbf{X} that equally minimizes both objective functions z_1 and z_2 . Then, we have a vector optimization problem in which a solution $x \in \mathbf{X}$ is evaluated with respect to a vector $Z(x) = (z_1(x), z_2(x))$. The solution of the problem has consequently to be seen in the identification of all efficient outcomes or the Pareto-set \mathbf{S} , defined as follows [6]:

Definition 1. Dominance: $Z(x)$ is said to dominate $Z(x')$ iff

$$z_k(x) \leq z_k(x') \quad \forall k = 1, \dots, K \wedge \exists k \mid z_k(x) < z_k(x').$$

We denote the dominance of $Z(x)$ over $Z(x')$ with $Z(x) \preceq Z(x')$.

Definition 2. Efficiency, Pareto-optimality: The vector $Z(x)$, $x \in \mathbf{X}$ is said to be efficient iff $\neg \exists Z(x'), x' \in \mathbf{X} \mid Z(x') \preceq Z(x)$. The corresponding alternative x is called Pareto-optimal and the set of all alternatives is the Pareto-set \mathbf{S} .

3 Methods

This section describes the Non-dominated Sorting Genetic Algorithm-II (NSGA-II) developed by K. Deb in [8] and its adaptations to tackle the particular problem we have that hand. In addition, the concept of hyper-heuristics and the set of

selection and placement heuristics used during the solution process with our model are described in section 3.2.

3.1 NSGA-II

In this paper we use the NSGA-II algorithm to build general MOHs (this process is described below). The NSGA-II is part of the so called Multi-Objective Evolutionary Algorithms (MOEAs) [6], which are methods well suited to solve multi-objective problems given their natural way of produce a set of Pareto-optimal non-dominated solutions within a single run. The NSGA-II is one of the best known and with good behavior MOEAs, used as a reference for many works in multi-objective optimization; that is the motivation for us to integrate it in our model. In this algorithm, initially a random parent population \mathbf{P}_0 of size N is created. The population is sorted based on the non-domination. Each solution is assigned a fitness (or rank) equal to its non-domination level (1 is the best level, 2 is the next-best level, and so on). Thus, minimization of this rank is assumed. The normal binary tournament selection, recombination, and mutation operators are used to create an offspring population \mathbf{Q}_0 of size N . After that, a combined population $\mathbf{R}_t = \mathbf{P}_t \cup \mathbf{Q}_t$ is formed. Next, the population \mathbf{R}_t is sorted according to non-domination, forming the fronts $\mathbf{F} = \mathbf{F}_1, \mathbf{F}_2, \dots$. Since all previous and current population members are included in \mathbf{R}_t , elitism is ensured. Now, solutions belonging to the best non-dominated set \mathbf{F}_1 are of the best solutions in the combined population and must be emphasized more than any other solution inside it. If the size of \mathbf{F}_1 is smaller than N , all the members of the set \mathbf{F}_1 are chosen for the new population \mathbf{P}_{t+1} . The remaining members of the population \mathbf{P}_{t+1} are chosen from subsequent non-dominated fronts in the order of their ranking. Thus, solutions from the set \mathbf{F}_2 are chosen next, followed by solutions from the set \mathbf{F}_3 , and so on. This procedure is continued until no more sets can be accommodated. The new population \mathbf{P}_{t+1} is now used for selection, crossover, and mutation to create a new population \mathbf{Q}_{t+1} , and the process is repeated until a stop criteria is satisfied. The NSGA-II main loop is shown in Algorithm 1. Inside this main process, we have two important sub-

process, the fast-non-dom-sort procedure (shown in Algorithm 2), which fast sorts the current population in different non-domination levels; and the crow-dist-assignment procedure (shown in Algorithm 3), which measures the crowding-distance, a measure of density of solutions in the neighborhood, used to preserve the diversity among non-dominated solutions during the tournament selection and the population reduction phase.

Algorithm 1. NSGA-II main loop

```

1:  $Q_{t+1} \leftarrow \text{make-new-population}(P_t)$ 
2:  $R_t \leftarrow P_t \cup Q_t$ 
3:  $F \leftarrow \text{fast-non-dom-sort}(R_t)$ 
4:  $P_{t+1} \leftarrow \emptyset$ 
5:  $i \leftarrow 1$ 
6: while  $|P_{t+1}| + |F_i| \leq N$  and  $F_i \neq \emptyset$  do
7:   crow-dist-assignment( $F_i$ )
8:    $P_{t+1} \leftarrow P_{t+1} \cup F_i$ 
9:    $i \leftarrow i+1$ 
10: end while
11: sort( $F_i, \prec_n$ )
12:  $P_{t+1} \leftarrow P_{t+1} \cup F_i[1:(N-|P_{t+1}|)]$ 
13:  $t \leftarrow t+1$ 

```

Algorithm 2. crow-dist-assignment(I)

```

1:  $l \leftarrow |I|$ 
2: for all  $i$  do
3:    $I[i]_{\text{distance}} \leftarrow 0$ 
4: end for
5: for all  $objective_m$  do
6:    $I \leftarrow \text{sort}(I, m)$ 
7:    $I[1]_{\text{distance}} \leftarrow I[l]_{\text{distance}} \leftarrow \infty$ 
8:   for  $i=2$  to  $(l-1)$  do
9:      $I[i]_{\text{distance}} \leftarrow I[i]_{\text{distance}} + \frac{(I[i+1]_m - I[i-1]_m)}{f_m^{\max} - f_m^{\min}}$ 
10:   end for
11: end for

```

Algorithm 3. fast-non-dom-sort(P)

```

1: for all  $p \in P$  do
2:    $S_p \leftarrow \emptyset$ 
3:    $n_p \leftarrow 0$ 
4:   for all  $q \in P$  do
5:     if  $p \prec q$  then
6:        $S_p \leftarrow S_p \cup q$ 
7:     else if  $q \prec p$  then
8:        $n_p \leftarrow n_p + 1$ 
9:     end if
10:   end for
11:   if  $n_p = 0$  then
12:      $p_{\text{rank}} \leftarrow 1$ 

```

```

13:      $F_i \leftarrow F_i \cup p$ 
14:   end if
15: end for
16:  $i \leftarrow 1$ 
17: while  $F_i \neq \emptyset$  do
18:    $Q \leftarrow \emptyset$ 
19:   for all  $p \in F_i$  do
20:     for all  $q \in S_p$  do
21:        $n_q \leftarrow n_q + 1$ 
22:       if  $n_q = 0$  then
23:          $q_{\text{rank}} \leftarrow i+1$ 
24:          $Q \leftarrow Q \cup q$ 
25:       end if
26:     end for
27:   end for
28:    $i \leftarrow i+1$ 
29:    $F_i \leftarrow Q$ 
30: end while

```

3.2 Hyper-Heuristics

Hyper-heuristics deal with the process of choosing good single heuristics for solving the problem at hand. The idea is to discover a combination of single heuristics that can perform well on a whole range of problems and in such a way that one heuristic's strengths make up for the drawbacks of another ([2], [4], [18]). The rationale is that there is no a unique best single heuristic to solve well a wide range of instances of a problem type, since certain problems may contain features that would enable a specific heuristic to work well, but those features may not be present in other problems. Then, a combination of heuristics, selectively applied based on the features present in a problem, may work well on a large number of problems. This method has been used recently to solve a variety of problems like constraint satisfaction problems [1] and timetabling [3]. The idea of hyper-heuristics is shown in Figure 2, where, starting from a problem E , in a given state space, we apply the best single heuristic, this will transform the problem to a new state E' , where we can apply a new heuristic better appropriated for the new problem to transform the problem to another state E'' . The process is then repeated until a complete solution has been constructed.

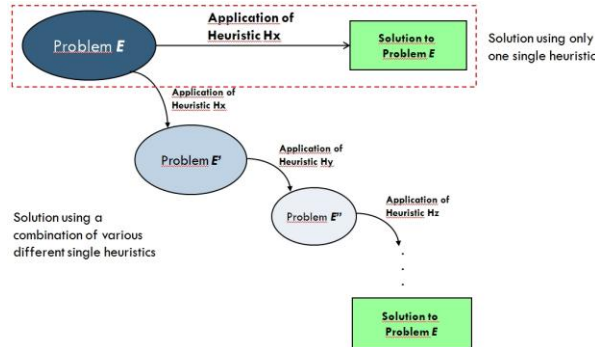

Fig. 2. Solution process for a problem using a combination of single heuristics

3.2.1 Single Heuristics

For the 2D irregular cutting-stock problem, the related single heuristics must define the exact location of the pieces inside the sheet. In this work two kinds of single heuristics to be combined by the Multi-Objective Hyper-Heuristics (MOHHs) were considered: one kind for selecting the pieces and sheets, and the other for placing the pieces into the sheets. The selection heuristics are shown below. Some of these heuristics are described in more detail in [18] and [13].

- **First Fit (FF):** Consider the opened sheets in turn in a fixed order and place the piece in the first one it fits.

- **First Fit Decreasing (FFD):** Sort pieces in decreasing order, and the largest one is placed according to FF.

- **First Fit Increasing (FFI):** Sort pieces in increasing order, and the smallest one is placed according to FF.

- **Filler + FFD:** Places as many pieces as possible within the open sheets. If at least one piece has been placed, the algorithm stops. The FFD algorithm is applied, otherwise.

- **Next Fit (NF):** Use the current sheet to place the next piece, otherwise open a new one and place the piece there.

- **Next Fit Decreasing (NFD):** Sort the pieces in decreasing order, and the largest one is placed according to NF.

- **Best Fit (BF):** This places the piece in the opened sheet where it best fits (i.e. with the minimum waste).

- **Best Fit Decreasing (BFD):** Same as the previous one, but sorting the pieces in decreasing order.

- **Worst Fit (WF):** It places the piece in the opened sheet where it worst fits (i.e. with the largest waste).

- **Djang and Fitch (DJD):** It places pieces in a sheet, taking pieces by decreasing size until the sheet is at least one third full. Then, it initializes w , a variable indicating the allowed waste, and looks for combinations of 1,...,5 pieces producing a waste w . If any combination fails, it increases w accordingly.

The placement heuristics, described in detail in [21], are the following:

- **Bottom-Left (BLI):** The piece starts at the top right corner of the sheet and it slides down and left with a sequence of movements until no other movement is possible. If the final position does not overlap the sheet boundaries, the piece is placed in that position. The heuristic does not allow a piece to skip around another placed piece. It's a simple and fast heuristic.

- **Constructive Approach (CA):** The heuristic starts by placing the first piece at the bottom and left of the sheet. Then, the next piece is placed in one of the five positions: $(\bar{x}, 0), (0, \bar{y}), (\underline{x}, \bar{y}), (\bar{x}, \bar{y})$ and (\bar{x}, \underline{y}) where $\bar{x}, \underline{x}, \bar{y}$ and \underline{y} are the maximum and minimum coordinates in x and y in relation to the first piece. For each position, the next piece slides following down and left movements, and the one that places the piece deepest (bottom and left) is chosen, except in special cases, such as when a hole is formed.

- **Constructive-Approach (Minimum Area) (CAA):** In this modification of the previous heuristic, the best position from the list is selected based on which one yields the bounding rectangle with minimum area, containing all pieces, and that fits in the bottom left corner of the object.

- **Constructive-Approach (Maximum Adjacency) (CAD):** With the first piece only the four corners of the sheet are considered. For the subsequent pieces, the possible points are the same than in CA. For each position in the list the piece starts in that position and its adjacency (i.e. the common boundary between its perimeter and

the placed pieces and the sheet edges) is computed. Then, the piece is slid down and left and the adjacency is computed again. The position with the largest adjacency is selected as the position of the new piece.

Using the previous selection and placement single heuristics, there are 40 different combinations for the action to be taken in each step of the solution process; these actions are shown Table 1.

Table 1. List of possible actions

4 Building Multi-Objective Hyper-Heuristics

In this work we adapted the evolutionary model proposed in [21], which produces general hyper-heuristics using a simplified representation of the state of the problem. A chromosome in the NSGA-II algorithm inside our model consists of a number of points in this simplified state space, each point being labeled with a given heuristic.

Under this schema, a chromosome represents a complete recipe for solving a problem, using this simple algorithm: until the problem is solved, (a) determine the current problem state E , (b) find the nearest point to it, (c) apply the heuristic attached to the point, and (d) update the state. The NSGA-II's task is to find a set S of Pareto-optimal chromosomes that are capable of obtaining good solutions for a wider variety of problems, taking into consideration the tradeoff

between the two minimization objectives defined in equations 1 and 2; the set of chromosomes in S are the MOHHs we are seeking.

4.1 Representation

Each chromosome is composed by a variable number of blocks. The initial number of blocks is randomly created and after it, the evolutionary process can create or delete blocks. Each block includes nine numbers. The first eight lie in the range 0 to 1 and represent the problem state, so a block can be seen as the labeled point. The label is the ninth number, which identifies a particular action (single heuristic). The NSGA-II's task is to create and evolve a certain number of such labeled points, using the problem-solving algorithm defined above, where to determine the nearest point we use Euclidean distance.

In the problem state, the first three numbers are related to rectangularity, a quantity that represents the proportion between the area of a piece and the area of a horizontal rectangle containing it. These numbers represent the fraction of remaining pieces with high rectangularity [0.9,1], medium rectangularity [0.5,0.9) and low rectangularity [0,0.5).

The fourth to seventh numbers are related to the area of pieces, and are categorized as follows (A_0 is the sheet area, A_p is the piece area): huge ($A_0/2 < A_p$); large ($A_0/3 < A_p < A_0/2$); medium ($A_0/4 < A_p < A_0/3$); and small ($A_p < A_0/4$). The eighth number represents the fraction of the total number of pieces that remain to be placed. The label is selected from all possible combinations of selection and placement heuristics showed in Table 1. Figure 1 shows a graphical representation of a chromosome using the simplified state space. This simplified feature space intends to represent the essential information about the geometry (rectangularity), and occupied and free space of the problem's whole configuration in a given step of the solution process.

Fig. 1. Graphical representation of a chromosome using the simplified state space

More features can be added or considered but with the corresponding increase in complexity. The current problem's state is compute in each step of the solution process, taking the information stored in the model about the pieces assigned, pieces free and open (available) sheets.

4.2 Fitness Function

Each MOHH is evaluated using two fitness functions, one for the waste of space in the sheet and another for the total time needed to place the pieces on the sheet. The waste of space in a given sheet and the corresponding fitness function are defined as:

$$W = 1 - \frac{\sum_{i=1}^k s(a_i)}{A_0} \quad (3)$$

$$FF_1 = \frac{\sum_{i=1}^m W_i^2}{m} \quad (4)$$

where k is the number of pieces inside the sheet, $s(a_i)$ the size of each piece, A_0 the size of the sheet and m is the number of sheets used. The second fitness function is defined as:

$$FF_2 = \sum_{i=1}^n t(h(a_i)) \quad (5)$$

Where $t(h(a_i))$ is the required time to place the piece a_i using the heuristic h . During the NSGA-II process, when a new individual (MOHH) is created (in the first parent population or in the subsequent children populations), a set of 5 problems is assigned to it. These problems are selected randomly from the training set. Then, the individual is evaluated with each problem using the previous fitness functions; the fitness values are added and averaged to obtain two final fitness values:

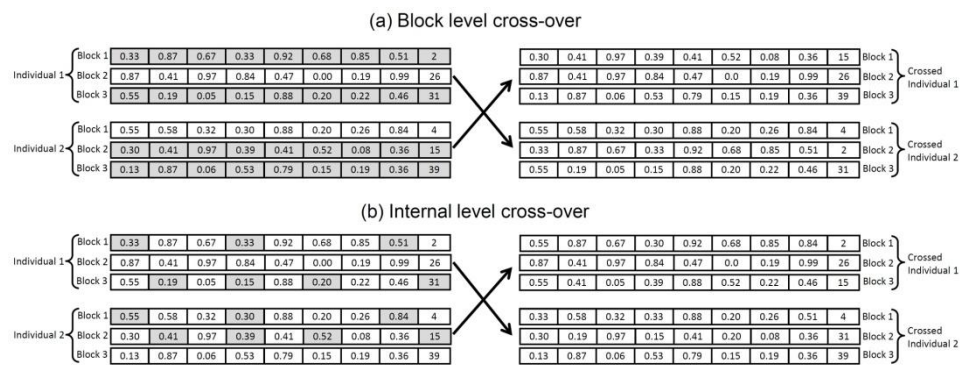

$$FFT_j(MOHH) = \frac{\sum_{i=1}^5 FF_j(p_i)}{5}; j = 1, 2 \quad (6)$$

Where p_i is the i -th problem assigned to the individual and index j indicates the number of fitness function. During the evolution, if an individual from the parent population survives for the next generation, a new problem is assigned to it and the fitness functions are recomputed.

$$FFT_j^l(MOHH) = \frac{(FFT_j^{l-1} n_p) + FF_j(p)}{n_p + 1}; j = 1, 2 \quad (7)$$

where FFT_j^l is the value of the j -th total fitness function for the generation l , n_p is the number of problems the individual has solved until now and $FF_j(p)$ is the value of the j -th fitness function for the new problem. This task of assigning new problems to old individuals and recompute their fitness values continue during the whole evolutionary process.

4.2 Genetic Operators

In this work we use two uniform versions of cross-over and mutation, the first version works at the block level and the second one works with the internal elements of each block. In the block level cross-over a random number of complete blocks is exchanged between two parent individuals to create two children individuals; since the number of blocks in each chromosome (individual) is variable, the random number is less or equal to the shortest chromosome. In the block level mutation, given certain probability, a randomly

selected block can be deleted from the chromosome or a randomly created block can be added to the chromosome. In the internal level cross-over and mutation, they select a random number of blocks and for each block a random number of values to be interchanged or mutate, depending on the operator. Examples of cross-over at block level and internal level are shown in Figure 2. Examples of mutation at block level and internal level are shown in Figure 3.

Fig. 2. Examples of cross-over operator at block level (a) and internal level (b)

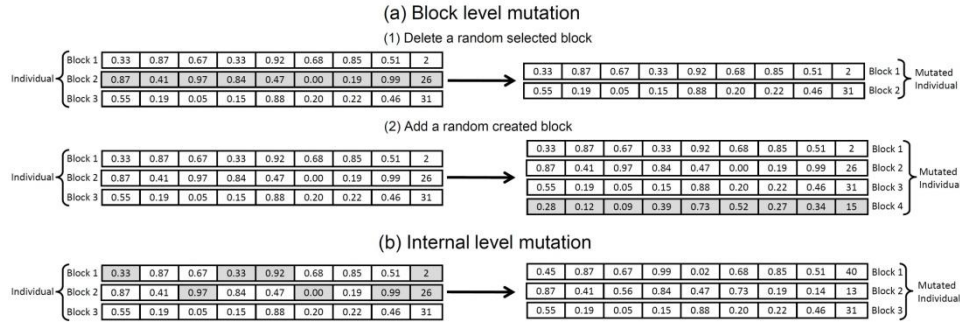

Fig. 3. Examples of mutation operator at block level (a), by deleting a random selected block (1) and adding a random created block (2); and at internal level (b)

5 Experimental Results

5.1 Problem Instances

For this work we generated 18 different types of problems, with 30 instances for each type, totaling 540 instances. Their characteristics can be seen

in Table 2. We also added a problem from the literature [Fujita, et al., 1993], which was scaled by a factor of 10 in order to have the sheet size of 300x300. Instances of type G are the only problems with unknown optimal number of objects, since they were produced after alterations to randomly generated problems with known optimum.

5.2 Experiments with the Proposed Model

The problem instances are divided into training and testing set. The NSGA-II is performed with the training set only, until a termination criterion is met and the set S of general MOHH's has been evolved. All instances in the testing set are then solved with each member of the set S and the results are recorded.

In order to test the overall performance of the model, various experiments were designed, which are described as follows:

- **Experiment A:** Instances are divided into two groups: Group A and Group B. Group A is the training set and is formed by instance types A, B,

C, D, E, F, G, H and I plus the Fu instance. After running our model over the training set, a set of Pareto-optimal MOHH were obtained and each one was tested with Set B (instance types J, K, L, M, N, O, P, Q and R).

- **Experiment B:** This experiment is similar to Experiment A, except that the training and testing sets are interchanged.

- **Experiment C:** This experiment takes the Fu instance and 15 instances from each problem type (from A through R) to form the training set. The remaining instances form the testing set.

- **Experiment D:** It is the same as Experiment C, except that the training and testing sets are swapped.

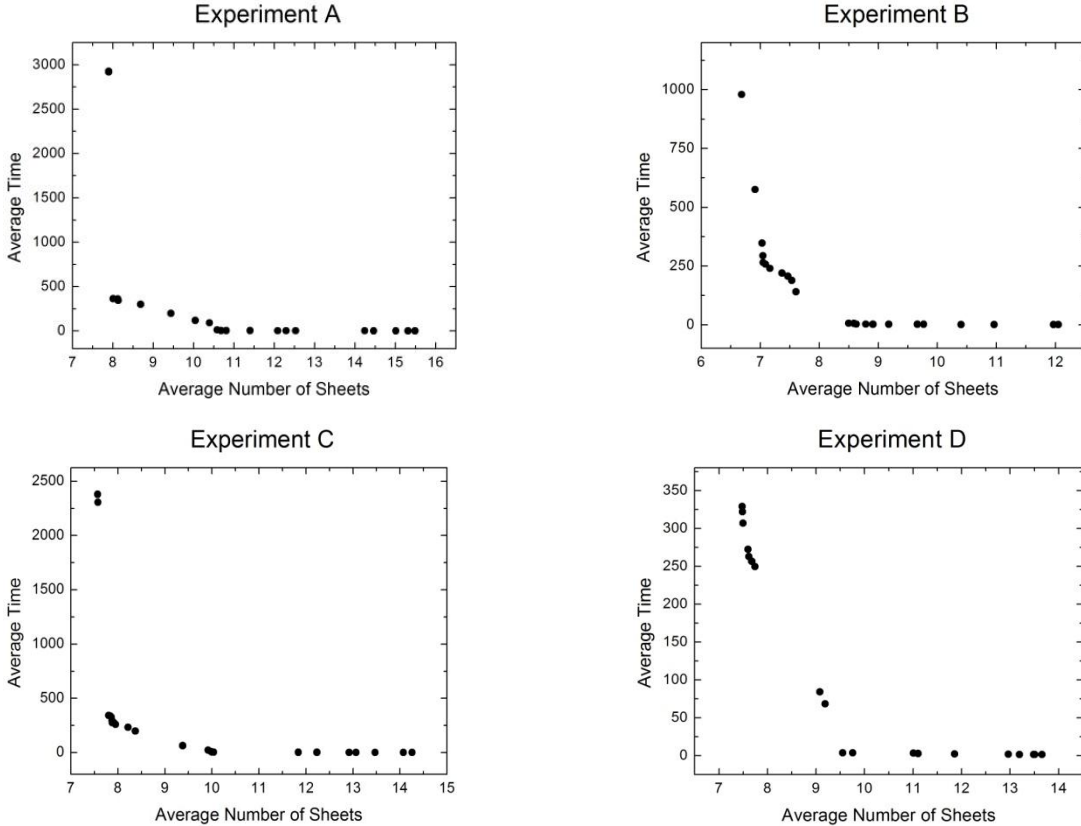

Fig. 4. Sets of non-dominated MOHHs (represented as points), built by the evolutionary process from NSGA-II, forming the Pareto-Fronts for experiments A, B, C and D

We performed three different and independent runs of the whole evolutionary process with NSGA-II for each experiment. The settings used for the different runs were for run 1, 36 individuals and 80 generations; for run 2, 36 individuals and

240 generations; and for run 3, 108 individuals and 80 generations; with all the runs sharing a mutation probability of 0.1 (applied to each individual) and a cross-over probability of 0.9. A single run of the evolutionary process for one of

the experiments using the settings of run 1, takes about 12 hours to approximate the Pareto-optimal set S , using our implementation in Java on a 2.8Ghz Core2Duro PC with 4Gb in RAM.

Each run produced as output a Pareto-optimal set $S_{\text{experiment;run}}$ containing about 24 MOHs for each experiment. Each one of the built MOHs is used to solve all the instances in the testing set, the results about the number of used sheets and the required time to place all the pieces are recorded and used later for comparisons. The sets produced for each run were then combined per experiment to obtain a unique single global set, having $S_A = S_{A1} \cup S_{A2} \cup S_{A3}$; $S_B = S_{B1} \cup S_{B2} \cup S_{B3}$; $S_C = S_{C1} \cup S_{C2} \cup S_{C3}$ and $S_D = S_{D1} \cup S_{D2} \cup S_{D3}$. The global set obtained from this combination contained about 70 MOHs; nevertheless, since the runs were performed independently, there were the probability of having solutions inside the global set that were dominated by other solutions, according to the non-dominance criterion given in Definition 2. Then, we run a final non-dominance filtering, using the results obtained by the MOHs on the testing set, and we selected only the non-dominated MOHs for each set, leaving about 20 final MOHs for each experiment.

Figure 4 presents the Pareto-optimal sets of MOHs resulting from the combination of the three independent runs and the filtering using the non-dominance criterion. These graphs summarize the behavior of the selected MOHs on solving all the instances in the testing set. Given the definition of equations 1 and 2, both objectives z_1 (number of sheets) and z_2 (time of placement) need to be minimized, then a point in the (minimum sheets, minimum time) corner would be the ideal solution; nevertheless, since the objectives are opposite to each other, that solution does not exist. From these plots we can easily observe the existent trade-off between the number of used sheets and the time required to place the pieces. The points more to the left tend to spend more time in the placement process but using less sheets, and the ones more to the right tend to do the placement very fast but using more sheets. It is possible to observe how significant improvements in z_1 can be achieved for "similar" values of z_2 , i.e. there are MOHs that solve the problems using fewer sheets with a little increase of time.

Since it is complicated to integrate in a single table all the MOHs built by the evolutionary process (about 20) for each experiment; we present in tables a selection of 12 MOHs from each set S , corresponding to each experiment. We selected these MOHs by taking the extremes of the fronts (the most right and the most left points in the above graphs) and the rest we selected randomly.

Tables 3, 4, 5 and 6 summarize the results for each one of the experiments, using the selected MOHs from each set S as described above. The second row of the tables represents the average normalized time a MOH needs to solve a problem, using its combination of single heuristics. The time is not in real time, but was measured by assigning a time score to each single heuristic, depending on the number of trials or movements it requires to place a piece inside a sheet; which in fact depends on the current configuration of the previous placed pieces in the sheet. These scores were assigned before the experiments, by solving all the problems with every single heuristic to know the performance of each one for every problem, where the most expensive heuristic has a value of 100, and the rest of the heuristics have a fraction of this time. When applying the MOH to solve a group of problems, for every heuristic used during the solution process its score is added and averaged at the end by the number of problems solved. The selected solutions are presented in the tables sorted in decreasing time.

Given a single problem instance, there is a single heuristic from the set of 40 single heuristics that solve it using the least number of sheets. Taking this as a baseline, the rest of the rows in the tables show the number of extra sheets a MOH needs to place all the pieces in comparison with that best single heuristic. The number in each cell is the percentage of problems where the MOH needs from -1 to more than 3 sheets to place all pieces with respect to the collection of best single heuristics. It is possible to observe how when a small number of extra sheets (-1 or 0) is needed, the time to perform the placement is big, and the opposite when the placement time is small the number of extra sheets is big, due to the conflicting objectives. This allows for a user to select the best solution in

accordance to his/her particular needs: fastness (large number of extra sheets), precision (small number of extra sheets) or equilibrium.

For experiment A the built Pareto-front presents a gap (shown in top left plot of Figure 4 and Table 3) between the left most point and the rest of the points, this is due to the testing set includes more diversity in the number of pieces and the optimum number of sheets, in comparison with the training set (as shown in Table 2). Then to solve a problem in the testing set is harder, and MOHs solving these problems using few sheets would tend to increase the solving time faster. Then, in the case of experiment B, we observe a more continuous

Pareto-front (top right plot of Figure 4 and Table 4), because of the opposite reason, to solve a problem in the testing set is easier given the less diversity, and MOHs solving these problems using few sheets do not need to increase too much the solving time.

For experiments C and D, there is a combination of problems from all the types and the diversity is present in both the training and the testing set. Given that, solutions from the testing set are equally harder to solve than the ones from the training set. In that sense, Pareto-fronts for experiments C and D could be complementary, and if we remove the two most left points of the front C (bottom left plot of Figure 4 and Table 5),

the rest of the MOHHs perform similarly in both experiments C and D (comparing bottom plots in Figure 4 and Table 5 and 6). The previous finding means that for experiment D, the algorithm is missing a couple of solutions more to the left, which in fact can be found if we add more runs of the algorithm.

Hyper-heuristics and multi-objective cutting are relative novel areas, then, the results presented in this work are in an early stage to be directly compared with other techniques, since there are still few works developed in the area, and no one about irregular cutting using the same objectives and the same set of problems.

6 Conclusions

In this paper we have described experimental results for a model based on the MOEA NSGA-II which evolves combinations of condition-action rules representing problem states and associated selection and placement heuristics for solving multi-objective 2D irregular cutting stock problems, where our goal was to minimize the (opposite) objectives of the number of sheets used to cut the set of pieces and the total time to place the pieces inside the sheets. These combinations of rules built by the model are called Multi-Objective Hyper-Heuristics (MOHHs). Four experiments were designed to test the validity of our approach, by creating sets of problems with different features like number of pieces, minimum number of sheets and irregularity of the pieces. In total 541 instances were created and split in 19 groups. Those groups were then divided in 4 groups of training and testing sets and the experiment were carried out using them. In general, the model efficiently build the set of Pareto-optimal MOHHs after going through the training phase using NSGA-II and the set of

training problems given for each experiment, and when applied to the unseen testing set of problems, those built MOHHs solve the problems efficiently taking in to account the trade-off between the two objectives. This trade-off between objectives was shown graphically by plotting the final built MOHHs, one objective versus the other, obtaining the shape of the Pareto-fronts for the different experiments. Additionally, results about how well each built MOHHs performs in comparisons with the collection of single heuristics were presented, in terms of percentage of problems solved better by the MOHHs and the time they used to solve the problems. Ideas for future work involve extending the proposed strategy to solve problems with more complex structure like 3D packing problems; including other objectives to be minimized, like the balance weight, the number of cuts or the heterogeneousness inside a sheet; or including other kinds of pieces with arbitrary shapes.
